17 **Abstract**

18 Local thermal environment has a strong influence on the physiology of marine ectotherms. This is
19 particularly relevant for tropical organisms living close to their thermal optimum, well exemplified by
20 the increasing frequency of bleaching occurrence in shallow-water corals. Mesophotic Coral
21 Ecosystems (MCEs) were suggested as potential oases, especially when they are submitted to internal
22 waves inducing short-term cooling events. Indeed, probability of bleaching occurrence in scleractinians
23 was reported to decrease with depth in Mo'orea as temperature variability increases. However,
24 ecophysiological data are currently lacking to understand the cause of lower susceptibility/increased
25 plasticity of deeper corals. A growing interest has been devoted the last decade to MCEs, but our
26 understanding of the physiological performance of benthic organisms living in this environment
27 remains relatively unexplored. To tackle that question, we first compared the metabolic responses
28 (dark respiration, net photosynthesis and photosynthetic efficiency) of the depth-generalist
29 scleractinian *Pachyseris speciosa* from two heterogeneous thermal environment (25 and 85m depths)
30 to acute heat stress to determine if the local thermal environment could predict coral response to
31 warming. Then, we tested the thermal performance of two sympatric species (the scleractinian *P.*
32 *speciosa* and the antipatharian *Stichopathes* sp.) to determine if there are inter-species differences in
33 performances in species experiencing identical levels of temperature variability, at mesophotic depths
34 (85m). Results revealed broader thermal performances in the mesophotic *P. speciosa* compared to
35 mid-depth ones, and constrained performances in the mesophotic antipatharian compared to the
36 scleractinian species. We hypothesize that the high fluctuations in temperature due to internal waves
37 in deeper areas contribute to the broader thermal performances of mesophotic *P. speciosa*. However,
38 the constrained performances of the mesophotic antipatharian compared to *P. speciosa* suggests that
39 other processes than the symbiosis with zooxanthellae also influence thermal performances of these
40 mesophotic organisms. Our results supported that *Stichopathes* sp. lives close to its thermal optimum,
41 suggesting a (relatively) cold thermal specialist strategy. In this context, composition of MCEs in the

42 future is unlikely to shift to antipatharian-dominated landscape and will remain coral-dominated
43 landscape.

49 **Introduction**

50 Janzen (1967) hypothesized that the physiological tolerance of each organism should be large enough
51 to encompass the entire gradient of conditions experienced throughout its life. This hypothesis
52 influenced theoretical models in suggesting that organisms from more variable climate should be
53 under selection for greater thermal acclimation ability than those from more stable climate (“The
54 climate variability hypothesis”; Angilletta, 2009; Ghalambor, 2006; Gunderson & Stillman, 2015;
55 Tewksbury et al., 2008). Evidence in favour with this hypothesis has been accumulating, with studies
56 indicating that tropical organisms have narrower thermal window of performance (Thermal breadth,
57 T_{br}) than temperate species, because their seasonal thermal range is smaller (Deutsch et al., 2008;
58 Gaston et al., 2009; Ghalambor, 2006; Huey et al., 2009; Sunday et al., 2012; Tewksbury et al., 2008).
59 However, contrasting evidence were also obtained and suggested to reflect the influence of
60 local/regional thermal variation in shaping thermal acclimation (Angilletta, 2009; Seebacher et al.,
61 2015; Shah et al., 2017a, 2017b). For example, experimental studies in the marine environment
62 showed differences in heat stress tolerance across reef sites characterized by contrasting levels of
63 thermal variability (i.e. fore-reef vs back-reef, inshore vs offshore reef ; Barshis et al., 2018; Kenkel et
64 al., 2013, 2015; Oliver & Palumbi, 2011).

65 Depth may also influence thermal variability, with shallow depths experiencing larger variations than
66 subjacent mesophotic depths, which have long been considered as cooler and more stable thermally
67 (Bongaerts et al., 2010; Glynn, 1996; Turner et al., 2019). Therefore, organisms from mesophotic
68 depths were hypothesized to have higher thermal sensitivities than shallow water ones (Smith et al.,
69 2016). This has been supported by some studies (Frates et al., 2021; Smith et al., 2016) but contrasting
70 evidence arose from physiological measurements and bleaching events (Frade et al., 2018; Gould et
71 al., 2021; Rocha et al., 2018). Now, thermal stability of mesophotic environments may be compromised
72 by cold water intrusions due to oscillations of water column isotherms, mixing, internal waves and
73 tides (Leichter et al., 2006, 2012, 2014; Sheppard, 2009; Wall et al., 2015; Wolanski et al., 2004; Wyatt
74 et al., 2020). Internal waves are created by the rise of cold and nutrient-rich waters being uplifted up
75 the reef slope, inducing thermal fluctuations at the time scale of hours to days which often exceed the
76 magnitude of temperature fluctuations in shallow waters (Godefroid et al., 2022; Leichter et al., 2012).
77 This cold water flushes to mesophotic depths may alleviate cumulated thermal stress during heat
78 waves, resulting, for instance, in reduced scleractinian bleaching (Pérez-Rosalez et al., 2021; Storlazzy
79 et al., 2020; Wall et al., 2015; Wyatt et al., 2020) but, to our knowledge, it has never been addressed
80 if such transient cold thermal variability resulted in increased thermal tolerance (wider T_{br}) of
81 mesophotic organisms.

82 Mesophotic Coral Ecosystems (MCEs) are characterized by the presence of light-dependent corals and
83 associated communities, typically from around 30m depth and extending up to 150m in certain regions
84 (Hinderstein et al., 2010; Lesser et al., 2009). In tropical zones, scleractinian corals usually dominate in
85 shallow waters (when conditions are appropriate), with some species extending their range to
86 mesophotic depths. Reef community composition progressively shifts with depth and non-
87 photosynthetic organisms become dominant when light conditions do not meet the requirements for
88 scleractinian photosynthesis (Pyle et al., 2019).

89 Among these, antipatharians are particularly abundant at mesophotic depths, sometimes forming
90 dense aggregations called Marine Animal Forests (MAFs, *sensu* Rossi et al., 2017), and even becoming

91 dominant at depth in several regions. Their role as habitat providers and nursery areas then become
92 fundamental to the maintenance of ecosystem functions (Bo et al., 2014, 2019; De Clippele et al., 2019;
93 Terrana et al., 2019). They differ from scleractinians because they are commonly referred to as
94 azooxanthellate, with only a few specimens showing the presence of
95 Symbiodiniaceae/Symbiodiniaceae-like cells (Bo et al., 2011; Gress et al., 2021; Wagner et al., 2011).
96 They also differ from scleractinians by their proteinaceous (and not calcareous) skeleton (Opresko et
97 al., 2014; Wagner et al., 2012).

98 To date, one study only has addressed the thermal sensitivity of a single antipatharian species and
99 revealed that it lives close to its T_{opt} (at least during the coldest months of the year) and has a rather
100 narrow T_{br} (tropical mesophotic *Stichopathes* sp., 15 days of exposure; Godefroid et al., 2022). This
101 experiment was conducted in the island of Mo'orea in French Polynesia, which is known to be
102 characterized by strong internal wave activity that impacts reef slopes at depths $\geq 30\text{m}$ around
103 the entire island (Leichter et al., 2012). Superimposed on seasonal temperature changes of
104 approximately 3°C , internal waves create a pattern of high frequency temperature variation
105 that is created by the arrival of cold and nutrient rich waters (Leichter et al., 2012). The
106 amplitude of these fluctuations increases with depth and are modulated across seasons, with
107 markedly higher internal waves activity from Oct-May than from Jun-Sep (Godefroid et al.
108 2022, Leichter et al. 2012, Pichon, 2019, Wyatt et al. 2020). Over a 40-days period during the
109 cold season (Oct-Nov 2019), which coincides with the period of high internal wave activity,
110 mean daily temperature fluctuations were twice as large at 90m than at 20m and the total
111 temperature range over this period was 4.6°C at 90m vs 2.9°C at 20m (Godefroid et al. 2022).
112 This indicates that mesophotic depths in Mo'orea are more variable than shallow-water ones,
113 at least during the cold season (Godefroid et al., 2022).

114 The aim of the present study was first to assess how the thermal physiology of a generalist coral living
115 from mid-depth (25m) to mesophotic (85m) environment, characterised by distinct temperature
116 regimes (warmer and less variable in shallower part of the reefs), varies along the depth gradient in
117 Mo'orea. We established TPCs for respiration, photosynthetic efficiency (F_v/F_m) and net photosynthesis
118 (P_{net}) of these two populations of *Pachyseris speciosa* living in different environments, using a short-
119 term ramping method. We hypothesized that TPCs should differ across the depth gradient, with lower
120 T_{opt} and wider T_{br} for mesophotic *P. speciosa* than for mid-depth ones. Secondly, we investigated the
121 thermal performance of two sympatric species (the scleractinian *Pachyseris speciosa* and the
122 antipatharian *Stichopathes sp.*) exposed to identical thermal regime (mesophotic zone, 85m). We
123 established TPCs for respiration (both species), photosynthetic efficiency (F_v/F_m) and net
124 photosynthesis (*P. speciosa*), their shapes and positions, to investigate the inter-specific variation of
125 thermal strategy in mesophotic environment. Understanding thermal performance strategy and
126 plasticity of key benthic organisms living in mesophotic areas will be an asset to better predict how
127 climate change will shape the future of the reefs from shallow to mesophotic areas.

128

129 **Materials and Methods**

130 *Coral collection and acclimation*

131 Coral colonies were collected on the outer reef slope on the North shore of the island of Mo'orea
132 (17°28'41.7''S, 149°51'09.9''W). The fore reefs on the North coast of Mo'orea are characterized by a
133 gentle slope (40-60°) from the surface down to 70-80m depth, where it drops almost vertically
134 (inclination of 60% or more) (Pérez-Rosales et al., 2021). Between 30 and 70m depth, the substrate is
135 mainly covered by sedimentary deposits, known as the "sandy plain", which is virtually devoid of sessile
136 benthos, except in some parts where there is an almost continuous monospecific cover of the
137 substratum (up to 70-80%) by *Pachyseris speciosa*, over large areas (Pichon, 2019). *P. speciosa* is a

138 keystone mesophotic species that is very common and widespread in the Society and Tuamotu
139 Archipelagos (Pichon, 2019).

140 On February 11th, 2021, the team of technical divers from *Under The Pole* expeditions
141 (<https://www.underthepole.com/>) collected eight colonies of the antipatharian *Stichopathes* sp. and
142 eight colonies of the scleractinian *P. speciosa* on a vertical slope at 85m depth. For the taxonomic
143 determination of *Stichopathes* sp., preliminary analyses targeted the nuclear Internal Transcribed
144 Spacers of the ribosomal DNA (ITS1) and suggested this *Stichopathes* sp. to be part of clade C as
145 described in Bo et al. (2012). All colonies were immediately transported to the “Centre de Recherches
146 Insulaires et Observatoire de l’Environnement” (CRIOBE), fragmented on the same day (two fragments
147 per colony for *Stichopathes* sp. and four fragments per colony for *P. speciosa*) and placed in an open-
148 circuit and sand-filtered aquarium with parameters of the collection site (Volume: 200L, Temperature:
149 26°C, salinity: 35.5). Light was controlled using Aquallumination Hydra lamps (USA) in the blue
150 spectrum (4-15 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$). The same day, eight colonies of *P. speciosa* were also collected
151 at 25m depth (gentle slope inclination), on the same site than the mesophotic colonies (17°28’41.7’’S,
152 149°51’09.9’’W). They were transported to the CRIOBE and immediately fragmented (four fragments
153 per colony) and placed in another sand-filtered aquarium with parameters of the corresponding site
154 (Volume: 200L, Temperature: 28°C, salinity: 35.5, light: 200-250 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ in the baseline
155 spectrum). These depths (25 and 85m) were selected as 25m corresponds to the upper bathymetric
156 range of *P. speciosa* in Mo’orea, extending at least up to 85m, corresponding to the upper bathymetric
157 range of *Stichopathes* sp., while remaining accessible to technical divers. A complete characterization
158 of the thermal environment of this site at different depths was reported in Godefroid et al. (2022) The
159 surface area of the *P. speciosa* fragments was measured using a high-quality 3D scanner (EinScan-SP
160 Scanner, Shining 3D, China). The black and reflective properties of the skeleton prevented the use of
161 the scanner for *Stichopathes* sp., so its surface area was calculated based on the surface formula of a
162 cylinder. Surface areas of the fragments were $5.1 \pm 0.3 \text{ cm}^2$ (n=21) for *Stichopathes* sp., $79.9 \pm 3.9 \text{ cm}^2$
163 (n=24) and $71.2 \pm 2.3 \text{ cm}^2$ (n=26; mean \pm se) for *Pachyseris speciosa* 25 and 85m, respectively.

164 The fragments were left five days to recover and then temperature in both aquaria was gradually
165 decreased/increased by 0.5°C/day to reach a final common temperature at 27°C (i.e. the acclimation
166 temperature). 27°C was selected as it is the average temperature between both depths at the time of
167 collection and it is within the annual range of temperature for both depths. When the target
168 temperature of 27°C was reached, the fragments were left to acclimate to these new conditions for at
169 least ten days before starting the ramp experiments. The experiment time schedule is depicted in
170 Figure 1a.

171

172 *Aquarium conditions*

173 Once at the target acclimation temperature (27°C), the only parameter that differed between the
174 aquaria was light, and all other parameters were manipulated identically. Both aquaria were open-
175 circuit, with seawater pumped at 25m depth in the Bay in front of the facilities and sand and UV
176 filtered. Temperature was manipulated using water chillers (one per aquarium, TECO TK1000, Italy)
177 and light was provided using Aqualllumination Hydra (one per aquaria, USA) following the natural diel
178 cycle. From 05:30 to 10:00 am, light was ramped up to a maximum (around 200-250 $\mu\text{mol photons m}^{-2}$
179 s^{-1} , using the baseline spectrum provided by the Aqualllumination Hydra lamps, for 25m and 4-15
180 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, in the blue spectrum, for 85m), which was maintained until 2 pm, before ramping
181 down to total darkness at 6 pm. Light intensity was selected based on *in situ* data from 20 and 90m
182 collected using light loggers (DEFI2-L, JFE Advantech Co., Japan). As *Stichopathes* sp. depends on
183 heterotrophic feeding, both aquaria were fed daily with a mix composed of live *Artemia salina*,
184 copepods and phytoplankton.

185 The respirometry experiments were run in a separate system composed of an open-circuit buffer tank
186 (150 L) where the temperature was manipulated, connected with a pump system to an experimental
187 tank (55 L) where the respirometry chambers were installed for the respirometry analyses. The
188 experimental tank was overflowing into the buffer tank and excess seawater in the buffer tank was

189 removed from the system by overflow. The buffer tank and the experimental tank were equipped with
190 circulation pumps to ensure a complete homogenisation of the temperature in both tanks. The high
191 volume of seawater (200 L) in the system and the fact that temperature was only manipulated in the
192 buffer tank allowed maintaining a very stable temperature in the experimental tank at all stages of the
193 experiments. Moreover, the open-circuit system ensured that the accumulation of catabolism and
194 stress molecules or mucus produced by the fragments during respirometry measurements would be
195 eliminated between each measurement period, thus allowing good water quality throughout the
196 experiments. Temperature in the buffer tank was controlled using one chiller (TECO TK2000, Italy) and
197 three titanium heaters (Schego, Germany), each connected to a temperature controller (ITC-308,
198 Inkbird, China). This allowed increasing water temperature quickly between the experimental stages.
199 A bubbling system was installed in the experimental tank to increase seawater aeration.

200

201 *Thermal ramping assays*

202 Ramp experiments were performed to determine the TPCs of respiration (R_{dark} ; *Stichopathes* sp. and
203 *P. speciosa*), photosynthesis (P_{net}) and photochemical efficiency (F_v/F_m) (*P. speciosa* only as
204 *Stichopathes* sp. does not host zooxanthellae). Each ramp experiment was divided in two legs, both
205 starting at the acclimation temperature: a hot ramp (27, 28, 29, 30, 31, 32°C) and a cold ramp (27, 26,
206 25, 24, 23°C). Four experiments were performed in the dark to assess the TPCs for R_{dark} and F_v/F_m . One
207 fragment from eight *Pachyseris speciosa* 25m colonies, eight *Pachyseris speciosa* 85m colonies and
208 eight *Stichopathes* sp. colonies was used for the hot ramp and another (from the same colony) for the
209 cold ramp. This way, a fragment was only used in a single hot ramp experiment (and was not reused)
210 and another fragment from the same colony for the cold ramp. In total, eight independent replicates
211 (colonies) per species/population were tested for each leg of the ramp experiment, with paired (from
212 the same colony) replicates between cold and hot ramps.

213 Ramp experiments were performed similarly under light to assess the TPCs for P_{net} . As light intensity
214 decreases with depth, distinct ramps were performed for *P. speciosa* 25m and 85m, at the respective
215 light intensities used for the acclimation period. One hot and one cold ramp were performed on
216 fragments from 5 colonies for *P. speciosa* 25m and the same on fragments from 5 colonies for *P.*
217 *speciosa* 85m. So, a total of 5 independent replicates (colonies) per population were tested for each
218 leg of the ramp experiment, with paired (from the same colony) replicates between cold and hot
219 ramps.

220 Each ramp experiment proceeded similarly, with six cycles of a hot ramp (on day 1), followed by a cold
221 ramp (on day 2) performed on another fragment from the same colonies. For example, in the case of
222 the hot ramp experiments in the dark, six coral fragments were moved from their aquarium at about
223 6 am to one of the eight respirometry chambers that were held in the experimental tank at 27°C (Fig.
224 1b). After 1 hour of acclimation in either dark or light conditions (i.e. light intensity corresponded to
225 the maximum light intensity used in the acclimation tank), the chambers were closed and oxygen
226 consumption was measured for 40 min to estimate R_{dark} or P_{net} . Then, the chambers were opened in
227 the experimental tank (allowing water exchange between the water in the chambers and from the
228 experimental tank) and F_v/F_m was measured in triplicate for each fragment (only in the dark
229 incubations) before increasing the temperature to the next target temperature (+1°C), for one hour
230 (i.e. 30-min temperature increase and 30-min of acclimation to the new temperature). Then, the
231 chambers were sealed again to start a new 40-min measurement period to estimate R_{dark} or P_{net} . The
232 same procedure was repeated until the full range of experimental temperatures had been tested (up
233 to 32°C), after which temperature was decreased back to 27°C in one step (i.e. the acclimation
234 temperature) and new measurements of oxygen consumption were taken after 2.5 (around 7 pm) and
235 12 hours (the next morning) to evaluate the recovery capacity of the fragments (Fig. 1b). Between the
236 end of the ramp experiment and the 2.5 and 12h "recovery" measurements, chambers were opened
237 and water exchanged with the water of the experimental tank. For the cold ramp experiments, the

238 same procedure (acclimation, measurement of R_{dark} or P_{net} , then F_v/F_m) was followed at 27, 26, 25, 24
 239 and 23°C but the recovery capacity was not assessed at the end.

240

241

242 **Figure 1.** (a) Time schedule of the experiments with coral collection and fragmentation, post-
 243 fragmentation recovery (5 days), temperature increase/decrease to reach the common temperature
 244 at 27°C (2 days), acclimation at 27°C (10 days) and experimentation (hot and cold ramps, 13 days). (b)
 245 Schematic representation of a hot ramp with (1) 1 hour dark acclimation, (2) 9 hours of hot ramping
 246 assays (respirometry and photosynthetic efficiency (F_v/F_m) measurements, at 27, 28, 29, 30, 31 and
 247 32°C) and (3) 15.8 hours of recovery assay (the water temperature is brought back to 27°C and
 248 measurements of oxygen consumption rates are taken 2.5 and 12 hours after the last test at 32°C).

249

250 *Metabolic responses*

251 Metabolic rates (R_{dark} and P_{net}) were determined by measuring changes in dissolved oxygen
252 concentration in eight respirometry chambers simultaneously. Measurements were taken every 5 s
253 using fiber-optic oxygen sensors connected to two 4-channel Fiber Optic Oxygen Transmitter (OXY-4
254 SMA G2 and OXY-4 SMA G3, Pre-Sens Precision Sensing GmbH, Germany), and were measured as
255 saturation level (%) using the software PreSens Measurement Studio. The eight respirometry chambers
256 varied in volume according to the species: fragments of *Stichopathes* sp. (unbranched, long and thin
257 corallum) were placed in Falcon tube of ~50 mL and fragments of *P. speciosa* (flat and thin) were
258 placed in plastic chambers of ~200 mL. In each chamber, an oxygen sensor spot (PreSens SP-PSt3-
259 NAU-D5-YOP-SA) was glued and calibrated according to the supplier's manual and a magnetic stir bar
260 was used (and separated from the fragment by a mesh) to maintain constant homogenization of the
261 water in the chamber. The chambers were submerged in a recirculating water bath (as previously
262 mentioned) which was placed on top of eight individual magnetic stirring plates allowing the constant
263 functioning of the magnetic stir bars in the chambers. Oxygen saturation was recorded in a blank
264 chamber (free of coral fragment) during each measurement and two blank chambers were used when
265 the two types of chambers (50 mL and 200 mL) were used during the same experiment (dark ramps).
266 These blanks allowed measuring the background respiration (i.e. the part of the respiration attributed
267 to the seawater microbes). At the end of the measurements, the surface area of the fragments was
268 measured as previously described. Oxygen saturation measurements were normalized based on the
269 volume of seawater in the experimental chambers (V), calculated from the density of seawater (Millero
270 & Huang, 2009; Millero & Poisson, 1981). Oxygen saturation was then converted to oxygen
271 concentration and the rate of oxygen consumption (VO_2) was calculated from the slope of its linear
272 regression ($[O_2]_{t_0} - [O_2]_{t_1}$) with time (t):

273
$$VO_2 = \left\{ \left[([O_2]_{t_0} - [O_2]_{t_1}) * \frac{V}{t} \right] - \left[([O_{2,blank}]_{t_0} - [O_{2,blank}]_{t_1}) * \frac{V_{blank}}{t} \right] \right\} * \frac{1}{SA}$$

274 Oxygen consumption rate of the fragments was corrected according to the consumption rate of the
275 seawater-only chamber and normalized using the surface area (SA) of the fragments, and was
276 expressed in micromole of oxygen per square centimetre per hour.

277 At the end of each metabolic rate measurements, all respirometry chambers were opened in the
278 experimental tank and the performance of the *Symbiodiniaceae* hosted by fragments of *P. speciosa* was
279 quantified by measuring their photochemical efficiency (F_v/F_m), in triplicate per fragment. These
280 measurements were repeated at each temperature of all ramp experiments performed in the dark
281 using a pulse-amplitude modulation fluorimeter (Diving-PAM, Walz, Germany). Dark-acclimated F_v/F_m
282 should decrease if the symbionts become thermally stressed (Aichelman et al., 2019; Fitt et al., 2001;
283 Thornhill et al., 2008; Warner et al., 1996). P_{gross} , the total amount of oxygen produced by the
284 fragments, was calculated by adding R_{dark} to P_{net} .

285

286 *Statistical analyses*

287 All data were analysed using the statistical software R version 1.3.959 (R Core Team, 2020).

288 Non-linear least-square regression models were fitted to the variables R_{dark} for *Stichopathes* sp. and
289 F_v/F_m for *P. speciosa*, using a symmetrical Gaussian function (as recommended by Angilletta, 2006, and
290 widely used since, see e.g. Rodolfo-Metalpa et al., 2014, Jurriaans et al., 2019, 2020) with the R package
291 *nlstools* (Baty et al., 2015):

$$292 \quad P = Pf_{max} * \exp\left(-0.5 \left(\frac{T - T_{opt}}{T_{br}}\right)^2\right) \quad (1)$$

293 where P is the physiological response, Pf_{max} is the maximum value of that response, T_{opt} is the
294 temperature at which the response value is maximal (i.e. the mean of the Gaussian function) and T_{br} is
295 the breadth of the response curve (i.e. the standard deviation of the Gaussian function). Significant
296 differences between the parameters Pf_{max} , T_{opt} and T_{br} were defined as non-overlapping 95%
297 confidence intervals.

298 Simple linear regression models ($y = ax + b$) were fitted to the variables R_{dark} , P_{net} and P_{gross} for *P.*
299 *speciosa*, with temperature as independent variable (n=10). Comparison of slopes were performed
300 using the R package *lsmeans* (Russel, 2016).

301 As R_{dark} data were not modelled identically for *Stichopathes* sp. (Gaussian curve) and *P. speciosa* (Linear
302 regression), thermal sensitivity was compared by calculating the temperature coefficient Q_{10} (i.e. the
303 proportional change of respiration in response to a temperature increase of 10°C) using the van't Hoff
304 equation:

$$305 \quad Q_{10} = \left(\frac{R_2}{R_1} \right)^{\left[\frac{10}{T_2 - T_1} \right]}$$

306 where R_1 and R_2 are the rates of oxygen consumption corresponding to low temperature (T_1) and high
307 temperature (T_2), respectively. Q_{10} was calculated in the range 23-32°C for *P. speciosa* and 23-28°C for
308 *Stichopathes* sp. (in the range of linear increase with temperature). Q_{10} values were first calculated for
309 each individual colony between consecutive temperatures and these were then averaged per
310 population. Q_{10} is typically around 2-3 for physiological processes; a lower Q_{10} indicates that respiration
311 rates were less sensitive to increasing temperatures, whereas a higher Q_{10} indicates higher thermal
312 sensitivity.

313 Analysis of residuals was carried out for all regression analysis. No trend in residuals was evidenced.

314 Recovery capacity for each variable and *P. speciosa* population was evaluated using two-factor mixed
315 model ANOVA, with population and time as fixed cross factors and fragment as a random repeated
316 subject (Doncaster & Davey, 2007). When the interaction was significant, a post-hoc Tukey's test was
317 performed using the appropriate mean square error. R_{dark} for *Stichopathes* sp. was analysed separately
318 using one-factor ANOVA with Time as fixed factor, as the surface values of the two studied species
319 were highly different due to their distinct morphologies (voluminous and flat vs. thin and filiform),
320 which strongly influenced the R_{dark} value after normalisation.

321

322 Results

323 *Metabolic responses with temperature*

324 Dark respiration (R_{dark}) increased linearly with temperature for *P. speciosa* living at 25m (mid-depth
325 colonies) and 85m (mesophotic colonies) (Figure 2a, b; Linear regression, $p < 0.001$ for both species,
326 Table S1). However, the rate of increase (i.e. the slope of the regression) is significantly higher for the
327 mid-depth than for the mesophotic colonies (Comparison of slopes, $p < 0.05$, Table S2). For *Stichopathes*
328 sp., R_{dark} data can be fitted by a nonlinear Gaussian relationship with temperature (Figure 2c). T_{opt} was
329 calculated at 29.6°C, corresponding to a maximum R_{dark} of 0.2 $\mu\text{mol O}_2 \text{ cm}^{-2} \text{ h}^{-1}$ (Table S3). Q_{10} was
330 calculated in the linear part of the regression (before T_{opt} for *Stichopathes* sp.) to allow comparing the
331 three groups (*P. speciosa* 25m, 85m and *Stichopathes* sp.). Q_{10} did not differ between depths and
332 stayed around 2-3 for *P. speciosa*, but was much higher and variable for *Stichopathes* sp. ($45.68 \pm$
333 61.96 , mean \pm sd $n=6$) (Table 1).

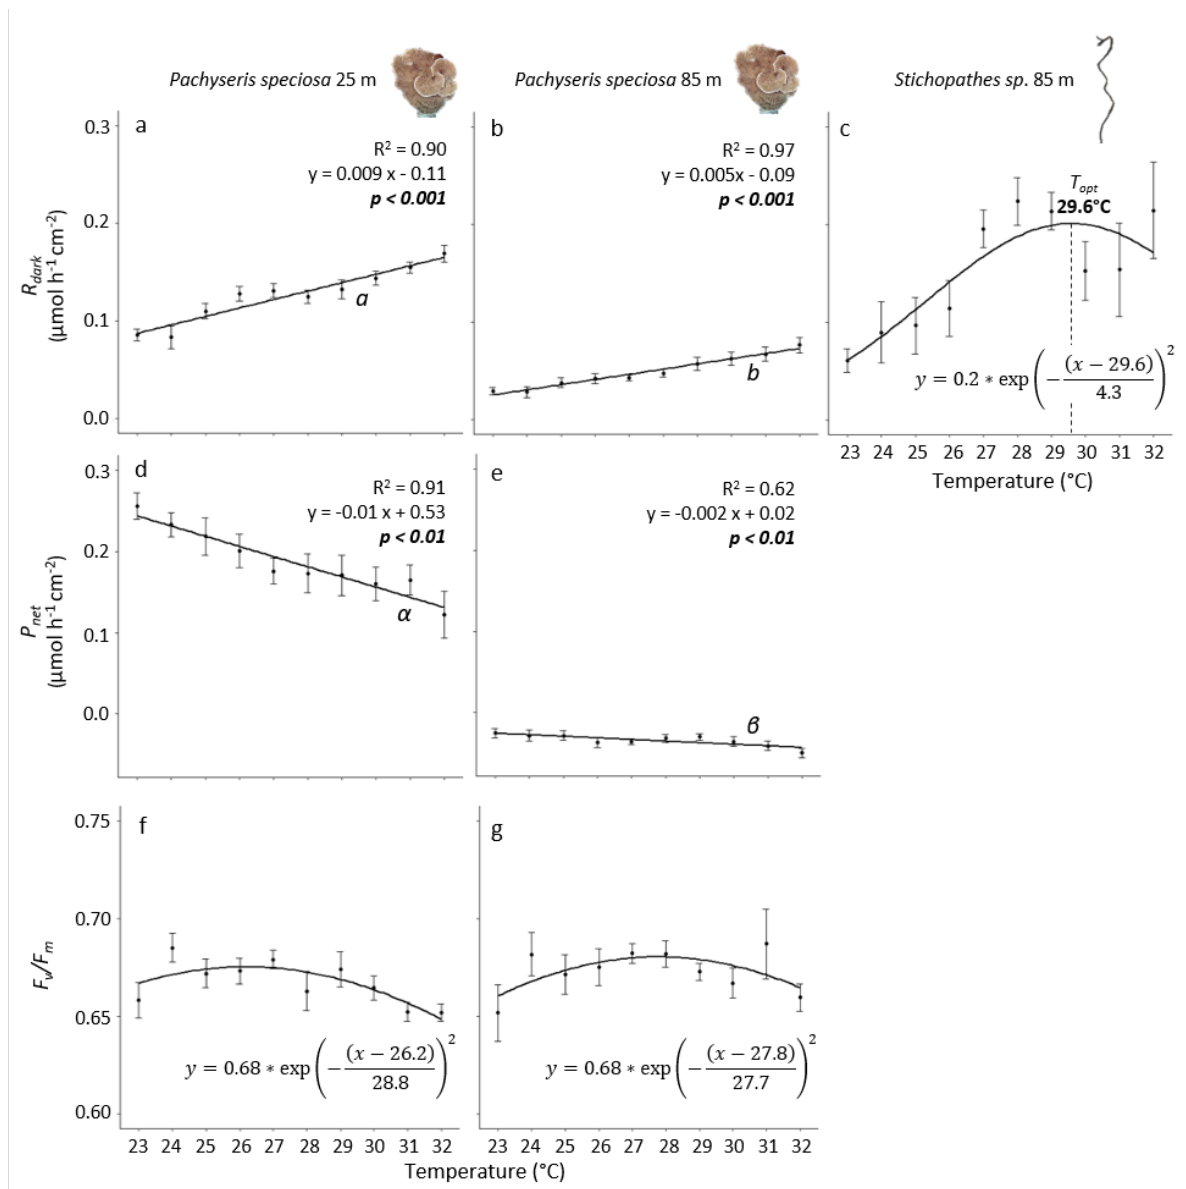

334 Absolute values of Net Photosynthesis (P_{net}) were positive at all temperatures for *P. speciosa* 25m but
335 were negative for the mesophotic fragments of *P. speciosa* (Figure 2d, e). At both depth, P_{net} decreased
336 linearly with temperature (Linear regression, $p < 0.001$ for *P. speciosa* 25m and $p < 0.005$ for *P. speciosa*
337 85m; Table S1) but the decrease was significantly more important for the mid-depth fragments
338 (Comparison of slopes, $p < 0.05$; Table S2).

339 The compensatory effect of P_{net} on R_{dark} was assessed by calculating gross photosynthesis. P_{gross} tended
340 to decrease linearly with temperature for mid-depth fragments and increased significantly for
341 mesophotic ones (Linear regression, $p > 0.05$ for *P. speciosa* 25m and $p < 0.001$ for *P. speciosa* 85m; Table
342 S1). Comparison of slopes revealed that depth had significant influence on P_{gross} ($p < 0.001$), but
343 temperature did not ($p > 0.05$; Table S2).

344 Photosynthetic efficiency (F_v/F_m) can be fitted by a nonlinear Gaussian relationship with temperature,
345 for fragments of *P. speciosa* from both depths (Figure 2f, g). The T_{opt} was 26.2°C for the mid-depth
346 fragments and 27.8°C for the mesophotic ones (corresponding to maximum yields of 0.68 for both

347 depths). However, confidence intervals overlapped for all the estimated parameters (T_{opt} , T_{br} , $F_v/F_m \max$)
 348 for *P. speciosa* 25 and 85m, indicating no significant differences between the two populations for these
 349 parameters (Table S3).

 353 (f, g) Photosynthetic efficiency (F_v/F_m) for (a, d, f) *P. speciosa* 25m, (b, e, g) *P. speciosa* 85m and (c)
 354 *Stichopathes sp.* Datapoints are the mean values \pm se (n=5-8). Data were modelled using simple linear

355 regression ($y = ax + b$) or nonlinear regression, Gaussian curve, using equation (1). p -values of each of
 356 the 3 parameters of the Gaussian regressions (c, f, g) are shown in Table S3.

357

358 **Table 1.** Q_{10} (mean \pm sd) value for oxygen consumption rate with temperature, calculated for *P.*
 359 *speciosa* 25m, 85m and for *Stichopathes* sp. (n=6-8)

	<i>P. speciosa</i> 25m	<i>P. speciosa</i> 85m	<i>Stichopathes</i> sp.
Q_{10}	2.26 \pm 0.42	3.29 \pm 1.36	45.68 \pm 61.96

360

361 *Recovery capacity after the ramping*

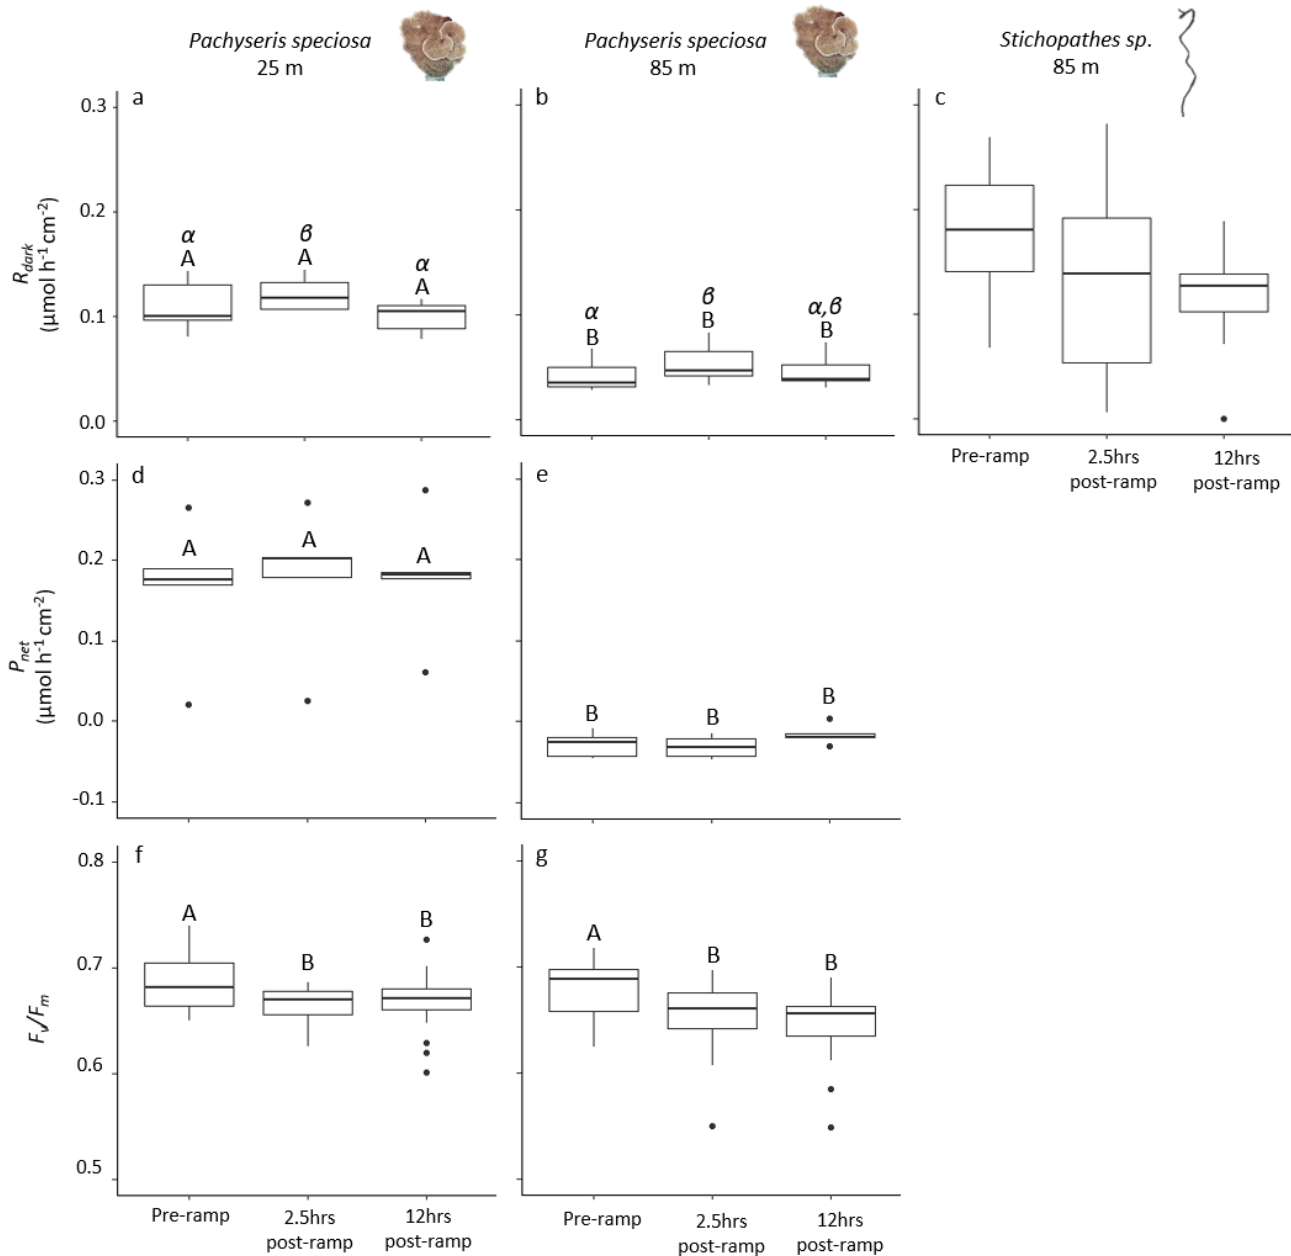

362 Recovery capacity was assessed by comparing measures at acclimation temperature before ramping
 363 and 2.5 and 12h after ramping and getting back to the acclimation temperature. R_{dark} of *P.speciosa*
 364 significantly differed according to depth (Mixed model ANOVA, $p_{depth}<0.001$), time ($p_{time}<0.001$) and
 365 the interaction of these factors ($p_{depth * time}=0.015$) Values of R_{dark} were significantly higher for the mid-
 366 depth fragments of *P. speciosa* than for the mesophotic ones, at acclimation temperature (27°C) and
 367 all recovery stages ($p_{Tukey}<0.001$; Figure 3a, b; Table S5). In addition, 2.5 hours after being brought back
 368 to acclimation temperature, fragments of *P. speciosa* from all depths had a significantly higher
 369 respiration rate than before the ramping ($p_{Tukey}=0.048$ for *P. speciosa* 25m and $p_{Tukey}=0.028$ for *P.*
 370 *speciosa* 85m), but a respiration rate not significantly different from that before the ramping was
 371 reached after 12 hours for both populations ($p_{Tukey} \geq 0.112$). For *Stichopathes* sp., there were no
 372 significant differences between R_{dark} pre-ramping and post-ramping recovery measurements
 373 ($p_{time}=0.075$) (Figure 3c, Table S4).

374 Absolute values of P_{net} were significantly higher for the mid-depth colonies of *P. speciosa* than for the
 375 mesophotic ones (Mixed model ANOVA, $p_{depth}<0.001$; Table S5). The P_{net} of mesophotic *P. speciosa* is
 376 so low (around zero) than no effect can be observed. No significant differences were highlighted

377 between P_{net} values pre-ramping and post-ramping recovery nor the interaction between time and
378 depth ($p_{Time}=0.144$, $p_{Time*depth}=0.462$) (Figure 3d, e, Table S5).

379 Photosynthetic efficiencies (F_v/F_m) of fragments of *P. speciosa* did not differ according to depth (Mixed
380 model ANOVA, $p_{depth}= 0.370$) but were significantly reduced after 2.5 and 12 hours of recovery post-
381 ramping ($p_{Time}<0.001$; $p_{Tukey} \leq 0.013$); the two latter did not differ ($p_{Tukey} > 0.083$; Figure 3f, g; Table S5).

382

31...
 384 **Figure 3. Recovery capacity** of (a,d,f) *P. speciosa* 25m, (b,e,g) 85 m and (c) *Stichopathes sp.* Metabolic
 385 performances of the coral fragments (n=5-13) before the ramp experiment (27°C, pre-ramp) and after
 386 the ramp experiment, when brought back to 27°C for 2.5 and 12 hours (post-ramp). Uppercase letters
 387 indicate significant differences between *P. speciosa* 25 and 85m. Greek characters indicates significant
 388 differences within a population according to time (Mixed model ANOVA with repeated measures on
 389 one cross factor). One-factor ANOVA did not reveal any statistical difference for *Stichopathes sp.*
 390 (Tables S4, S5).

391

392 **Discussion**

393 Ongoing ocean warming is increasingly damaging coral reefs and evidence of mass mortality events
394 are multiplying. Researchers have suggested that depth may provide refuge from events occurring at
395 shallower depth, as heat accumulation decreases with increasing depth (Turner et al., 2019). Yet,
396 evidence from experimental studies, oceanographic thermal models and bleaching events are mixed
397 (Frade et al., 2018; Frates et al., 2021; Gould et al., 2021; Pérez-Rosales et al., 2021; Rocha et al., 2018;
398 Smith et al., 2016; Venegas et al., 2019; Wall et al., 2015). Differences in sensitivity across depths can
399 be attributed to differing environmental conditions and/or species physiological capacities (Page et al.,
400 2019). While abiotic differences across depths have been addressed multiple times, intrinsic metabolic
401 differences have not yet received much attention (Ferrier-Pagès et al., 2022).

402

403 *Pachyseris speciosa* 25m vs. 85m

404 In this study, we assessed the thermal performance of the photosynthetic scleractinian *Pachyseris*
405 *speciosa* from distinct depths (25 and 85m). Given the cooler mean temperatures and highly
406 fluctuating thermal conditions (owing to internal waves) at mesophotic depths in Mo'orea (Leichter et
407 al., 2012; Godefroid et al., 2022), we expected that mesophotic colonies of *P. speciosa* would have
408 lower T_{opt} and wider T_{br} compared to mid-depth colonies. T_{opt} was not reached by specimens from both
409 depths for respiration and photosynthesis: performances increased linearly with temperature, so we
410 could not determine T_{opt} nor T_{br} for *P. speciosa*. This is likely related to the experimental protocol used:
411 longer exposure time or further temperature increase (above 32°C) could allow achieving T_{opt} . Despite
412 this, the effect on performances (i.e. the slope or the rate of activation, E_a) was higher on mid-depth
413 than on mesophotic colonies, suggesting that mesophotic colonies have a higher capacity to
414 encompass large range of temperatures and will be less affected by temperature regimes higher than
415 T_{opt} , compared to their mid-depth congeners.

416 Symbiont density, that was not assessed in the present study, might be one of the factors influencing
417 depth-specific thermal performance in terms of respiration. Photoacclimatation is a well-known
418 process in corals, allowing to maintain efficient performance in distinct light intensity regimes. In low
419 light environment as in mesophotic depths, contrasting results were reported, showing in some cases
420 an increase, decrease or stable symbiont density (Fitt et al., 2000; Leletkin et al., 1996; Mass et al.,
421 2010; Padilla-Gamino et al., 2019; Smith et al., 2017). Our data revealed a higher photosynthetic rates
422 (P_{net}) in mid-depth than in mesophotic fragments, which may be due to higher symbiont density and/or
423 chlorophyll pigments. Differences in thermal performance across depths could also be related to the
424 composition in Symbiodiniaceae, but previous research in Mo'orea showed that *Symbiodiniaceae* and
425 bacterial communities did not differ across depths (6-120m) for *P. speciosa* (Rouzé H., unpublished
426 results).

427 Photoacclimatation is not the main or single driver modulating the capacity of corals to thrive under
428 fluctuating environmental conditions. Other parameters, such as changes in colony morphology or in
429 the contribution of heterotrophy, through feeding, are also known to differ across depths (Kahng et
430 al., 2019). In the present study, we did not characterize the heterotrophic contribution of corals along
431 the depth gradient. So, we cannot exclude that the heterotrophic energy input through feeding, that
432 is known in some cases to represent an important contribution in the mesophotic corals (Kahng et al.,
433 2019), will affect thermal performance. Further research will be required to determine the role of
434 photo-physiological capacities and heterotrophy into the performance of corals from distinct depths.

435 Another factor that is likely to influence the thermotolerance of *P. speciosa* from different depths is
436 the adaptation and/or acclimatization of the corals to the local temperature regime. A large body of
437 research on scleractinian corals showed that thermal history, in particular temperature variability,
438 affects coral physiological tolerance under heat stress (Barshis et al., 2018; Castillo & Helmuth, 2005;
439 Guest et al., 2012; Kenkel et al., 2013, 2015; Oliver & Palumbi, 2011; Safaie et al., 2018). However,
440 research that have experimentally compared thermal sensitivity of coral conspecifics from distinct

441 depths are relatively scarce. These studies either found no differences in thermal sensitivity across
442 depth (instantaneous acute heat stress, 5-10m vs 30-35m; Gould et al., 2021) or lower tolerance to
443 acute heat stress in mesophotic colonies (ramping of 1°C/day; Frates et al., 2021). Our study is the first
444 to present thermal performance of corals from lower mesophotic zone (45m at the deepest in previous
445 studies). We unravelled distinct thermal performance of mesophotic colonies compared to mid-depth
446 ones, with a broader thermal performance of mesophotic corals exposed to heat stress. Our results
447 therefore suggest that high temperature variability (owing to internal waves activity) at mesophotic
448 depths in French Polynesia likely contributes to the observed broader thermal performance of colonies
449 from those depths.

450 Q_{10} results did not differ between depths, which does not support the higher thermotolerance of
451 mesophotic colonies previously discussed based on the comparison of slopes between depths. This is
452 counterintuitive as Q_{10} derives from the slope, but this is due to the different methods of calculation.
453 Indeed, Q_{10} was first calculated on each individual subjected to the different temperatures and all Q_{10}
454 were then averaged (mean \pm sd), while slopes of the linear regressions were calculated based on all
455 data together (and not individual colonies first). Q_{10} value therefore provides an indication of the
456 variability of responses between depths, which was higher in mesophotic than in mid-depth colonies
457 (Table 1). This higher variability in mesophotic colonies could be explained by the more fluctuating
458 environmental conditions at these depths, and thus potentially a greater diversity in response
459 strategies to these fluctuating conditions, compared to the mid-depth colonies that are exposed and
460 have acclimated/adapted to more stable environmental conditions.

461

462 Comparing thermal performance of corals living at distinct depths has a real ecological interest if both
463 shallow and deep zones are impacted by heat stress (e.g. marine heatwaves). MCEs are often viewed
464 as areas of environmental stability, being spared by heat stress, which creates good conditions for the
465 development and survival of corals compared to their shallow-water counterparts. However, MCEs
466 may also be affected by heat stress and depending on the thermotolerance of corals living in these

467 areas, the consequences of heat stress affecting mesophotic reefs may be totally different. Although
468 long-term temperature data at 85m were not available in French Polynesia, data were available from
469 3 to 50m and included the 2019 mass bleaching event around Mo'orea. These data confirmed ours in
470 that temperature is colder and more variable in deeper areas of the reefs and they also revealed that
471 the 2019 marine heatwave did not spare mesophotic depth, with a clear rise in temperature in both
472 shallow and mesophotic areas (at least up to 50m; Fig. S1). This confirmed that mesophotic corals (at
473 50m) are impacted by heat stress and we could hypothesize that such heat stress was also present up
474 to 85m. The suspected presence of heat stress at 85m, combined with the broader thermal
475 performance of corals at 85m, support that mesophotic zone may serve as resistant oases (Guest et
476 al., 2018) that are able to tolerate thermal anomaly without losing coral cover due to specific traits of
477 the corals living there, as *P. speciosa*. We suggest that this is likely because mesophotic colonies,
478 exposed to more variable seawater temperatures, developed broader thermal performance to
479 withstand warming than their mid-depth congeners. This supports the assumption that mesophotic
480 environments exposed to large thermal fluctuations, such as caused by internal waves, will be an
481 important asset in the future from a management perspective, as they are most likely to be less
482 susceptible to global warming than their shallower counterparts. We acknowledge that this
483 observation of broader thermal performance of mesophotic corals was performed on a single species
484 using acute heat stress. More endpoints at longer time scale and other depth-generalist species should
485 be tested to confirm that pattern at a larger scale. In addition, even if bleaching was not observed *per*
486 *se*, the increase in metabolic activity can be interpreted as an increase in sensitivity of the process
487 (Silbiger et al., 2019), that could potentially lead to bleaching if exposure was extended over a longer
488 period.

489

490 In contrast with previous parameters, the effect of temperature on photochemical efficiency (dark
491 acclimated F_v/F_m) did not differ significantly between mid-depth and mesophotic colonies of *P.*
492 *speciosa*. The relationship F_v/F_m according to temperature was described by a Gaussian function, with

493 a maximum (T_{opt}) at 26.2 and 27.8°C (at 25 and 85m, respectively) beyond which it started decreasing.
494 Moreover, 12 hours post-recovery, photochemical efficiency of the *Symbiodiniaceae* was not fully
495 recovered, at any depths. It is well known that, in darkness, oxygen concentration declines significantly
496 in coral tissues due to chlororespiration, leading to hypoxic conditions that results in a decline in F_v/F_m
497 of the symbionts during the night (Shashar et al., 1993; Jones et al., 2001). However, the addition of
498 exogenous oxygen to hypoxic coral tissues (held in darkness for several hours), as was continuously
499 provided during the ramping, was showed to be sufficient to increase F_v/F_m back to normal values
500 (Jones et al., 2001). So, we suggest that this decline in F_v/F_m around T_{opt} is unlikely to be an
501 experimental artefact. Rather, we suggest that it shows the rapid thermal acclimation capacity of the
502 symbionts. Indeed, T_{opt} (maximum F_v/F_m) was measured around 27°C at both depth, which corresponds
503 to the acclimation temperature. This suggests that an acclimation of 10 days at the common
504 temperature of 27°C was sufficient for the *Symbiodiniaceae* to optimize their photochemical efficiency.

505

506 *Pachyseris speciosa* vs. *Stichopathes* sp. from the same depth (85m)

507 At mesophotic depths, scleractinian corals co-exist with other cnidarians, including antipatharians. The
508 present study revealed distinct metabolic performances under thermal stress between *P. speciosa* and
509 *Stichopathes* sp. collected from the same site at 85m depth. Indeed, T_{opt} for dark respiration was
510 reached for *Stichopathes* sp. but not for *P. speciosa* and the higher sensitivity of *Stichopathes* sp. was
511 also supported by its high Q_{10} value, much out of the typical range of 2-3 for thermochemical enzymatic
512 reactions. Does that mean that *Stichopathes* sp. from Mo'orea is a (relatively) cold thermal specialist
513 and that its bathymetric range (from 60m and deeper) is constrained by temperature? Indeed, a
514 previous study of the same species showed that a 15d thermal exposure to 1°C above T_{opt} induced
515 deleterious effects (Godefroid et al., 2022). Reanalysing the data of Godefroid et al., (2022), using the
516 same Gaussian regression as in the present study, yielded a T_{opt} of 28.3°C and a T_{br} of 2.15°C. In the
517 present ramping experiment, T_{opt} was higher (29.6°C) and T_{br} was wider (4.26°C) than in Godefroid et
518 al. (2022), which is likely a consequence of seasonal acclimation, as the sampling was performed during

519 different sampling periods (February 2021 vs. October 2019 in Godefroid et al., 2022), which differed
520 in temperature (Figure S1). This mismatch could also be partly explained by the acute nature of the
521 stress performed, preventing acclimation to occur. Indeed, studies have previously showed that acute
522 ramping methodologies tend to overestimate T_{opt} in comparison with medium/long-term methods
523 (Schulte et al., 2011; Sinclair et al., 2016). Yet, differences in TPC metrics between the two
524 experimental approaches used (medium-term exposure in Godefroid et al., 2022 vs acute ramping in
525 the present study) were not significant (overlapping confidence intervals for each parameters, T_{br} , T_{opt}
526 and Pf_{max}). This indicates that the method used has limited influence on the results, supporting the use
527 of acute ramping methodologies for antipatharians (especially in a comparative approach).

528

529 **Conclusion**

530 No consensus currently exists as if Mesophotic Coral Ecosystems may or not provide resistant and/or
531 resilient coral oases to the increasing frequency of heat stress events. MCEs in Mo'orea were suggested
532 to play a role as short-term resistant oases from bleaching (Pérez-Rosales et al., 2021). Our study
533 contributed to this statement by providing the first metabolic evidence of a broader thermal
534 performance of the depth-generalist scleractinian *P. speciosa* at mesophotic depths compared to mid-
535 depth, which suggests the capacity of that species to adopt a thermal strategy depending on local
536 temperature regime. This supports that mesophotic environments exposed to large thermal
537 fluctuations are most likely to be more tolerant under global warming. Surprisingly, our work also shed
538 light on the constrained thermal performance of antipatharian compared to scleractinian, living in a
539 similar site at mesophotic depth (85m). This has important implication for predicting the future of
540 mesophotic reefs, as it unravelled that other biological processes than the *Symbiodiniaceae* symbiosis
541 may modulate the thermal performance of benthic organisms in that particular zone of the reefs.
542 Regarding the lack of plasticity of antipatharian compared to scleractinian in response to heat stress,

543 it is unlikely to observe a shift of dominance from scleractinian to antipatharian in future mesophotic
544 reefs.
